Solving Inequalities and Proving Farkas's Lemma Made Easy

David Avis and Bohdan Kaluzny

March 20, 2003

1 Introduction

Every college student has learned how to solve a system of linear equations, but how many would know how to solve $Ax \leq b$ for $x \geq 0$ or show that there is no solution? Solving a system of linear inequalities has traditionally been taught only in higher level courses and is given an incomplete treatment in introductory linear algebra courses. For example, the text of Strang [4] presents linear programming and states Farkas's lemma. It does not, however, include any proof of the finiteness of the simplex method or a proof of the lemma. Recent developments have changed the situation dramatically. Refinements of the simplex method by Bland [1] in the 1970s lead to simpler proofs of its finiteness, and Bland's original proof was simplified further by several authors. In this paper we will use a variant of Bland's pivot rule to solve a system of inequalities directly, without any need for introducing linear programming. We give a simple proof of the finiteness of the method, based on ideas contained in the paper of Fukuda and Terlaky [3] on the related criss-cross method. Finally, if the system is infeasible, we show how the termination condition of the algorithm gives a certificate of infeasibility, thus proving the Farkas Lemma. Terminology and notation used here follows that of Chvátal's linear programming book [2].

We consider the following problem. Given a matrix $A = [a_{ij}] \in \Re^{m \times n}$, and a column vector $b \in \Re^m$, find $x = (x_1, x_2, ..., x_n)^T$ that satisfies the following linear system, or prove no such vector x exists:

$$\begin{aligned} Ax &\leq b \\ x &\geq 0 \end{aligned} \tag{1}$$

We will illustrate a simple method to do this on the following example:

$$\begin{aligned} -x_1 - 2x_2 + x_3 &\leq -1 \\ x_1 - 3x_2 - x_3 &\leq 2 \\ -x_1 - 2x_2 + 2x_3 &\leq -2 \\ x_i &\geq 0 \qquad \text{for } i = 1, 2, 3. \end{aligned} \tag{2}$$

We first convert this system of inequalities into a system of equations, by introducing a new nonnegative *slack* variable for each inequality. This slack variable represents the difference

between the right and left-hand side of the inequality. In our example, we need three new variables which we label x_4, x_5, and x_6. Putting these variables on the left-hand side, and the others on the right-hand side we have the following system:

$$\begin{aligned} x_4 &= -1 + x_1 + 2x_2 - x_3 \\ x_5 &= 2 - x_1 + 3x_2 + x_3 \\ x_6 &= -2 + x_1 + 2x_2 - 2x_3 \end{aligned} \tag{3}$$

It is easy to see that if we have any nonnegative solution of (2) then it extends to a nonnegative solution to (3) by defining the slack variables by their respective equations. Conversely a nonnegative solution of (3) when restricted to x_1, x_2 and x_3 gives a solution to (2). We call a system of equations such as (3) a dictionary. The variables on the left-hand side are called *basic* and the variables on the right-hand side are called *cobasic*. We get a *basic solution* to the equations in (3) by setting all the cobasic variables to zero and $x_4 = -1, x_5 = 2, x_6 = -2$. Unfortunately this is not a nonnegative solution. The algorithm proceeds as follows: it finds the smallest-indexed basic variable that is set to a negative value. In this case it is x_4. In the equation for x_4 we find the cobasic variable with the smallest index that has a positive coefficient. In this case it is x_1. We solve this equation for x_1 and substitute for x_1 in the other equations. This yields a new dictionary:

$$\begin{aligned} x_1 &= 1 - 2x_2 + x_3 + x_4 \\ x_5 &= 1 + 5x_2 - x_4 \\ x_6 &= -1 - x_3 + x_4 \end{aligned} \tag{4}$$

The step we performed is called a *pivot* operation, and is the basic step of the algorithm. In fact it is the only step: we simply repeat this operation. In (4), first set the cobasic (i.e. right-hand side) variables to zero and get the basic solution $x_1 = 1, x_5 = 1, x_6 = -1$. Again, we find the variable with the smallest index and negative value, x_6. In the equation for x_6 we find the smallest-indexed variable with a positive coefficient, x_4. We pivot by solving this equation for x_4 and substituting for x_4 in the other equations, obtaining the dictionary:

$$\begin{aligned} x_1 &= 2 - 2x_2 + 2x_3 + x_6 \\ x_4 &= 1 + x_3 + x_6 \\ x_5 &= 0 + 5x_2 - x_3 - x_6 \end{aligned} \tag{5}$$

We are now in luck. The basic solution is nonnegative, and its restriction to our original three variables gives a feasible solution to (2): $x_1 = 2, x_2 = 0, x_3 = 0$. So far so good. An immediate question now is: what happens if there is no solution to the original problem? Let

us consider the following problem:

$$\begin{aligned} -x_1 + 2x_2 + x_3 &\leq 3 \\ 3x_1 - 2x_2 + x_3 &\leq -17 \\ -x_1 - 6x_2 - 23x_3 &\leq 19 \end{aligned} \tag{6}$$

We get our initial dictionary by introducing three slack variables and letting them be the basic variables:

$$\begin{aligned} x_4 &= 3 + x_1 - 2x_2 - x_3 \\ x_5 &= -17 - 3x_1 + 2x_2 - x_3 \\ x_6 &= 19 + x_1 + 6x_2 + 23x_3 \end{aligned} \tag{7}$$

The algorithm proceeds as before by choosing the equation for x_5 and solving for x_2:

$$\begin{aligned} x_2 &= 17/2 + (3/2)x_1 + (1/2)x_3 + (1/2)x_5 \\ x_4 &= -14 - 2x_1 - 2x_3 - x_5 \\ x_6 &= 70 + 10x_1 + 26x_3 + 3x_5 \end{aligned} \tag{8}$$

Now we find something new. We select the equation for x_4 and find that there is no cobasic variable with a positive coefficient. Let us rewrite this equation with all variables on the left-hand side, including those with zero coefficient, getting:

$$2x_1 + 0x_2 + 2x_3 + \mathbf{1}x_4 + \mathbf{1}x_5 + \mathbf{0}x_6 = -14 \tag{9}$$

This is an example of an *inconsistent equation*. Note that the coefficients of all variables are nonnegative, but the right-hand side is negative. Therefore this equation cannot be satisfied by choosing any combination on nonnegative values for the variables. This equation was derived from the original system by standard operations that do not change the solution set for the equations. Therefore (7) and hence (6) has no nonnegative solution. In fact (9) gives a simple proof of this coded in the bold face coefficients of the slack variables. We multiply each inequality in (6) by the coefficient of its corresponding slack variable and add them up getting:

$$\begin{aligned} \mathbf{1} * (-x_1 + 2x_2 + x_3 &\leq 3) \\ +\mathbf{1} * (3x_1 - 2x_2 + x_3 &\leq -17) \\ +\mathbf{0} * (-x_1 - 6x_2 - 23x_3 &\leq 19) \end{aligned} \tag{10}$$

$$\Rightarrow \mathbf{2x}_1 + \mathbf{2x}_3 \leq \mathbf{-14} \tag{11}$$

The final inequality, (11), is called an *inconsistent inequality*: all the variables have a nonnegative coefficient and the right-hand side is negative. The multipliers given by the coefficients of the slack variables are called a *certificate of infeasibility* for the original system.

We now have a complete description of the algorithm which we call the b-rule, for solving problems of form (1):

Step 1: Introduce m slack variables $x_{n+1}, ..., x_{n+m}$ and use these as the basis (left-hand side) of an initial dictionary:

$$x_{n+i} = b_i - \sum_{j=1}^{n} a_{ij} x_j \qquad\qquad i = 1, ..., m \tag{12}$$

Step 2: Set the cobasic (right-hand side) variables to zero. Find the smallest index of the basic (left-hand side) variables which receive a negative value. If there is none, terminate with a feasible solution.

Step 3: Find the cobasic variable in the equation chosen in Step 2 that has the smallest index and a positive coefficient. If there is none, terminate as the problem is infeasible. The coefficients of the slack variables give a certificate of infeasibility. Otherwise, solve this equation for this variable, and substitute in all of the other equations. Go to Step 2.

In what follows we prove the following:

- the algorithm described above terminates in a finite number of steps;
- if it terminates in Step 2, then the basic solution is feasible for (1);
- if it terminates in Step 3, then the system (1) is infeasible and the slack coefficients give a certificate of this.

2 Proof of Correctness

Theorem 1 *The b-rule is finite.*

Proof. Given an input system (1) we construct the initial dictionary (12) and run the b-rule algorithm. Since there are at most $\binom{n+m}{m}$ possible choices of a basis, if the algorithm is not finite then some bases must be repeated, a process called *cycling*. Let us assume that this can happen, and choose a system of equations that cycles.

First suppose that x_{n+m} ($n+m$ being the largest index) enters and leaves the basis during the cycle. When x_{n+m} is chosen to enter the basis we must have an equation of the following form, where we let B and N denote the set of basic and cobasic indices respectively:

$$x_k = -b'_k - \sum_{j \in N \setminus \{n+m\}} a'_{kj} x_j + a'_{k,n+m} x_{n+m} \tag{13}$$

Note the choice of x_{n+m} as entering variable in this equation implies that $-b'_k < 0$, $a'_{k,n+m} > 0$ and $a'_{kj} \geq 0$ for $j \in N \setminus \{n+m\}$. This shows that every solution to the full system of equations with $x_1, ..., x_{n+m-1} \geq 0$ must have $x_{n+m} > 0$.

Now consider when x_{n+m} is chosen to leave the basis. The dictionary has form:

$$x_i = b'_i + \sum_{j \in N} a'_{ij} x_j \qquad \text{for } i \in B \setminus \{n+m\} \tag{14}$$
$$x_{n+m} = -b'_{n+m} + \sum_{j \in N} a'_{kj} x_j$$

The choice of x_{n+m} ensures that $-b'_{n+m} < 0$ and $b'_i \geq 0$ for $i \in B \setminus \{n+m\}$. By setting the cobasic variables to zero, the above dictionary shows that there exists a solution to the system of equations with $x_1, ..., x_{n+m-1} \geq 0$ and $x_{n+m} < 0$. Clearly both situations (13) and (14) cannot hold, so there cannot exist a cycle during which the largest-indexed variable enters and leaves the basis.

Now suppose there exists a cycle where x_{n+m} always stays in the basis, then we can remove x_{n+m} and it's corresponding equation without changing the pivot decisions made during the cycle. Similarly, if there exists a cycle where x_{n+m} always stays in the cobasis, then we can remove x_{n+m} from all of the equations without influencing the cycle. Either way we can reduce original example that cycles to an equivalent example during which the largest-indexed variable both enters and leaves the basis. This will lead us to the two conflicting situations above, so a cycle cannot exist: the algorithm is finite. ■

Since the algorithm is finite, it must terminate in either Step 2 or Step 3. If it terminates in Step 2, we have a nonnegative solution to the original system. This follows from the fact that the only operations we performed on the initial dictionary were standard operations for manipulating a system of equations. If the algorithm stops in Step 3, we have a certificate of infeasibility which, when stated in general terms, is a variant of the Farkas Lemma.

Theorem 2 *(Farkas Lemma variant) Either there exists* $x \in \Re^n, x \geq 0$ *such that* $Ax \leq b$ *or there exists* $y \in \Re^m, y \geq 0$ *such that* $y^T A \geq 0, y^T b < 0$.

Proof. We begin by showing that there cannot exist both a vector x and a vector y satisfying the conditions of the theorem. For otherwise, $0 > y^T b \geq y^T A x \geq 0$. If such a vector x does not exist, the finiteness of the b-rule implies that the algorithm will terminate in Step 3. The algorithm returns an inconsistent equation:

$$\sum_{\substack{j=1, \\ j \neq k}}^{n+m} a'_{kj} x_j + x_k = -b'_k \tag{15}$$

where $b'_k > 0$ and all of the coefficients $a'_{kj} \geq 0$. Set $y_i = a'_{k,n+i} \geq 0, i = 1, ..., m$. We observe that equation (15) is obtained from the initial dictionary (12) by multiplying the equation for x_{n+i} by y_i and summing, for $i = 1, ..., m$. This is because variable x_{n+i} appears only once in the

entire dictionary, as the left-hand side of its defining equation. This shows that $y^T b = -b'_k < 0$, and

$$\sum_{i=1}^{m} y_i a_{ij} = a'_{kj} \geq 0 \qquad\qquad j = 1, ..., n \tag{16}$$

again by the termination condition of the algorithm. Hence $y^T A \geq 0$. ■

3 Conclusion

The b-rule is a finite algorithm that finds a nonnegative solution to a system of linear inequalities. Readers familiar with linear programming will recognize that the b-rule is the dual form of Bland's rule, [1] (see also [2]), with a zero objective (cost) row. Simple variants of the b-rule exist for finding a solution to $Ax \leq b$, or $Ax = b, x \geq 0$ etc. We can also use the b-rule to obtain algorithmic proofs of the Farkas Lemma and the Fundamental Theorem of Linear Inequalities. In practice, the b-rule can be used to find a starting primal-feasible basis for a linear program without having to introduce the traditional "phase-one" artificial variable. However, as with all pivot rules known, in the worst case it may require an exponential number of steps.
